

## RANKING OF BITUMINOUS MIXES

---

---

### 9.1 Preamble

Previous chapters assessed the performance of various bituminous mixes against several distresses. It was observed that it is difficult to rank the overall suitability of various mixes since the mix which performs well in a particular type of distress might perform poorly against the other. At present, there is no methodology that can be used for the logical prediction of the overall suitability of the mixes. Hence, a novel ranking method is proposed in this chapter to determine overall suitability ranking of all sixteen types of mixes, based on their laboratory results and possible field conditions. It would be helpful for the designers and field engineers to choose the most optimum type of filler and its content in the bituminous mix.

### 9.2 Details of Ranking Methodology

Testing of bituminous mixes in various aspects was done to estimate its suitability in that particular aspect (e.g., rutting). However, based on the obtained set of test results, it was very difficult to identify the mix, which should be considered as “best” in overall aspects. The term “best” is relative, and it not only depends on the properties of the material but also by the field conditions on the pavement site (Saboo et al., 2018). The bituminous mix that gives the best performance against particular distress (e.g., rutting) does not necessarily deliver similar performance against another distress (e.g., moisture sensitivity). Hence, it is critical to identify the crucial distresses in every scenario, and then select the best filler which forms distress resistant mix. For instance, in the scenario of possible waterlogging, it is logical to give priority to the

filler which form moisture resistant mixes with higher OBC over the filler which creates moisture susceptible mixes with lower OBC (much more economical). However, in case of arid regions with little or no rainfall, it is logical to choose filler which creates economical mixes. Hence, the designer must give suitable priority to each bituminous mix property to choose the overall best filler. This study proposed a simple methodology based on this principle to rank various mixes based on different test results of bituminous mixes. The brief outline of the method is provided below.

Step I: Representation of test results in form of parameter matrix

In this study, the performance of the 16 types of mixes (4 fillers  $\times$  4 filler contents) was assessed in 9 different primary test parameters (OBC, Marshall stability, Marshall quotient, indirect tensile strength, tensile strength ratio, active adhesion, passive adhesion, fatigue life, and Cantabro loss). The resilient modulus was not taken in the analysis since it was used in the calculation of pavement layer thickness and not in its performance assessment against any distress. Similarly, ageing indices were not taken in the analysis since ageing doesn't directly responsible for any distress. These results were represented in the form of a table or matrix of order  $16 \times 9$ , in which each cell represented an individual test result ( $R_{m,t}$ ) ( $1 < m < 16$  and  $1 < t < 9$ ) obtained in the corresponding test. The representative parameter matrix and the actual test matrix is shown in Table 9.1 and 9.2, respectively.

Step II: Preparation of normalized parameter matrix

It is commonly known that different tests generate results with different units (e.g., kN and seconds in case of Marshall Stability and active adhesion respectively), and hence there was a need to normalize all values to a standard scale. Each result value

( $R_{m,t}$ ) was normalized using the Equation 9.1. The normalized matrix is shown Table 9.3.

$$NV_{m,t} = \frac{R_{m,t} - \min R_{m,t}}{\max R_{m,t} - \min R_{m,t}} \times 100 \quad [9.1]$$

Where  $NV_{m,t}$  = Normalized result value

$R_{m,t}$  = Test result obtained experimentally in a particular test

$\max R_{m,t}$  = Maximum test result value

$\min R_{m,t}$  = Minimum test result value

### Step III: Assessment of possible field conditions and assigning priorities

Apart from material properties, external factors like traffic loading and environmental conditions also influence the performance of bituminous mixes. To consider the effect of these factors, sixteen different hypothetical scenarios were assumed by varying external parameters namely, vehicular load, traffic intensity, average pavement temperature, and rainfall intensity. Every factor is subdivided into two categories (high and low) to cover a wide spectrum of possible scenarios. P<sub>H</sub> indicated that the pavement site in consideration has the average ambient temperature greater than or equal to 40°C. At this temperature, the rutting is one of the most predominant distresses. Similarly, P<sub>L</sub> specified the pavement site which has average ambient temperature lower than or equal to 10°C. At this temperature, fatigue and low temperature cracking can be considered as dominant modes of pavement failure. Average annual rainfall intensity greater than 1200 mm is assumed as average high rainfall intensity (R<sub>H</sub>), while average annual rainfall intensity lower than 1000 mm is categorized as average low rainfall intensity (R<sub>L</sub>) (MoRTH, 2013).

A failure such as rutting is majorly observed in places having a predominance of overloaded vehicles (vehicles having a gross weight higher than legal limits). Hence, average heavy vehicle loading ( $V_H$ ) is assumed as pavements having a predominance of overloaded vehicles, while, average low vehicle loading ( $V_L$ ) is assumed in places having a predominance of vehicles way below than legal load limits. Finally, high traffic intensity ( $T_H$ ) and low traffic intensity ( $T_L$ ) is assumed in places having traffic intensity higher than 6000 and lower than 3000 commercial vehicles per day, respectively. For instance,  $P_L R_L V_L T_L$  signifies field conditions having with low ambient temperature, low average rainfall, low average vehicle loading, and low traffic intensity. Hence assuming every possible hypothetical scenario based on variation in each external factor, sixteen different possible scenarios were observed.

To determine the ranking of each mix it is necessary for a designer to assign priority value for each test. This priority was given to each test using priority value ( $P_t$ ) ( $1 \leq t \leq 9$ ).  $P_t$  is an integer that should start from 1 and whose maximum value was always less than or equal to 9. Test having lower  $P$  was assigned the higher priority and vice versa. The assignment of the priority to a particular test was done as per logical judgment of the designer. This could be understood by the following example. For instance, in case of  $P_L R_L V_L T_L$ , there is a very low possibility of failure due to rutting and overloading due to the lesser vehicle loading and lower average pavement temperature, hence lower priority values were assigned to Marshall Quotient and Marshall stability values. Similarly, lower priority values were assigned to tensile strength ratio and passive adhesion test results, because of lower possibility of moisture damage due to low rainfall. However, there is a relatively higher possibility of low temperature cracking due to low ambient temperature, hence higher priority

amongst all parameters was given to fatigue life and indirect tensile strength. The priority values assigned in all cases were displayed in Table 9.4.

Step IV: Calculation of Weightage Factors ( $F$ )

Based on the assigned  $P$  value, another parameter known as the weightage factor ( $F$ ) was calculated for each test as per Equation 9.2.

$$F_t = \frac{P_i}{\sum_{i=1}^9 P_i} \quad [9.2]$$

In some cases, it was required to assign the same priority to two test parameters ( $P_i = P_{i+p}$ ). In such cases, the same  $F$  values were yielded to both test parameters as per Equation 9.2. In the foregoing expression,  $\sum F_t = 1$ . In cases where the higher value of test result represented the superior mixes (Marshall stability, Marshall Quotient, indirect tensile strength, tensile strength ratio, passive adhesion, and fatigue life), weighing factor calculated as per Equation 9.2 is taken in analysis. However, in situations where lower test values represented a better mix (OBC, active adhesion, and Cantabro loss), the reciprocal of the obtained weightage factor was used.

Step V: Calculation of Ranked Values ( $RV$ ) and Total Rank Values ( $TRV$ )

Depending upon the assigned priority and the calculated weightage factor, the rank value ( $RV$ ) for each test parameter of every mix was determined as:

$$RV_{mt} = \frac{NV_{m,t}}{F_i} \quad [7.3]$$

Where,  $NV_{m,t}$  is the Normalized result value of each parameter ( $1 < m < 16$  and

$1 < t < 9$ )

The summation of  $RV$  of all 9 test parameters can be termed as the total rank value ( $TRV_m$ )

$$TRV_m = \sum RV_{m,t} \quad [7.4]$$

The mixes having higher  $TRV$  values are ranked as superior and vice versa. The assignment of priority values, calculation of weightage factor, and calculation of  $RV$  and  $TRV$  values for  $P_L R_L V_L T_L$  case is shown in Table 9.5. Similar to  $P_L R_L V_L T_L$ , different set of priority values were assigned for other cases, which in turn generated the other set of  $TRV$  values. In “ $n$ ” different possible cases produce “ $n$ ” different sets of  $TRV$  values for each mix. In this study, there are a total of 16 different cases, so, 16 sets of  $TRV$  values were calculated and shown in Table 9.6.

Step VI: Calculation of Global Total Rank Values ( $GTRV$ )

Finally, the summation of all “ $n$ ” different  $TRV$  values was done as follows:

$$GTRV = \sum_{i=1}^{i=n} TRV_i \quad [7.5]$$

Where,  $GTRV$  is termed as global test rank value of each mix, based on “ $n$ ” different sets of priorities. In this study, summation of all sixteen set of  $TRV$  values gave the  $GTRV$  of all mixes. The magnitude of  $GTRV$  was used to compare the overall performance of mixes in a much logical manner, in which mix having higher  $GTRV$  value corresponded to superior performance/ranking and vice versa.

Table 9.1 Table showing representative parameter matrix

| Type of Mix | Test Parameters |                    |                   |                           |                        |                 |                  |              |               |
|-------------|-----------------|--------------------|-------------------|---------------------------|------------------------|-----------------|------------------|--------------|---------------|

### 9.3 Ranking of Various Mixes

Based on the obtained *GTRV*, the final overall rankings of all mixes are given in Table 9.7. As per *GTRV* values, KS 8.5, GL 7 and KS 7 were proven to be amongst the three best performing mixes. All these mixes not only exhibited better strength, rutting, fatigue and cracking resistance, but also showed satisfactory moisture sensitivity, active adhesion, Cantabro loss at a relatively lower OBC. This was attributed to their fine nature and due to presence of adhesion promoter minerals like Calcite and Portlandite in their composition. GP 8.5, SD 4, and GP 7 were amongst the worst performing mix. Although GP mixes displayed good resistance against rutting, fatigue, and cracking than convention SD mixes, they also displayed abysmal performance in terms of moisture sensitivity and adhesions due to high silica content. They might be beneficially used in the regions having arid climates. It seemed that the utilization of fillers in large quantity (7 and 8.5%) produced bituminous mixes with overall superior performance. However, it is essential to choose the appropriate type of filler to ensure satisfactory performance of mixes.

Table 9.7 Overall ranking of various mixes

| Type of Mix | GTRV | Ranking |
|-------------|------|---------|
| KS 8.5      | 1070 | 1       |
| GL 7        | 1046 | 2       |
| KS 7        | 997  | 3       |
| SD 8.5      | 990  | 4       |
| GL 8.5      | 990  | 5       |
| SD 7        | 855  | 6       |
| GL 5.5      | 833  | 7       |
| KS 5.5      | 800  | 8       |
| GL 4        | 638  | 9       |
| GP 7        | 621  | 10      |
| SD 5.5      | 584  | 11      |
| GP 8.5      | 558  | 12      |
| KS 4        | 542  | 13      |
| GP 5.5      | 513  | 14      |
| SD 4        | 365  | 15      |
| GP 4        | 353  | 16      |

## **9.4 Summary**

This section proposed a novel ranking method assess based on the experimental properties of the mixes and priorities assigned by the designer, to assess overall suitability of bituminous mixes. This procedure of the method was explained and method was adopted to rank all sixteen types of mixes based on their overall performance. The final ranking suggested that the mixes prepared with KS and GL at higher filler contents deliver much superior performance than conventional SD mixes. On the other hand, GP mixes displayed overall poor performance. The proposed method can also be used by other researchers to analyze the other types of mixes.
